Introduction

Scaling and increasing the performance of the wireless communication systems in the 5 GHz frequency range required an increase in the allowed frequency channels number by additionally using the channels that were initially assigned only for military and meteorological radars. To reduce the impact of the wireless broadband systems on radars, the data exchange protocol included requirements for detecting radar signals and immediately clearing the operating frequency.

The implementation of the radar detection mechanisms was related to the air scanning methods and to the transition between the frequency channels. These methods were included in the requirements for the operation of the wireless systems and were called dynamic frequency selection (DFS).

Dynamic frequency selection and radar detection

It is necessary to point out the differences between the dynamic frequency selection technology and the radar detection mechanism:

- The dynamic frequency selection implementation requires scanning the available frequency channels and selecting the least noisy channel. Thus, DFS performs a uniform distribution of the wireless data transmission systems over the frequency spectrum.
- A radar detection mechanism is necessary to ban the use of the frequency channels on which radars are currently operating. Thus, the DFS technology retains the possibility of using such channels for the broadband wireless systems, as long as they are immediately released when radar is detected.

Regulatory requirements

Regulatory requirements for wireless communication systems vary by country. The most common requirements for the implementation of dynamic frequency selection and radar detection, were created by the Federal Communications Commission (FCC) and by the European Telecommunications Standards Institute (ETSI).

For the InfiNet devices, the regulatory limitations are performed by license which includes the set of frequencies and by the presence of the radar detection configuration option. A license may be issued in accordance with the regulations for a particular territory.

DFS operation principles

The dynamic frequency selection algorithm consists of the following steps:

1. Turn on the device.
2. Sequential channel scanning in accordance with the frequency grid. The scanning results are filled in the DFS table, where each channel is associated with the level of the detected signal.
   a. The maximum signal level for each frequency channel is recorded in the DFS table. To eliminate false positives, when assessing the signal level, its spectral density is also taken into account.
   b. By default, the scan duration on each frequency channel is 3 seconds and this parameter is configurable.
   c. The total scan duration depends on the number of channels in the frequency grid.
3. Analyze the DFS table and select the frequency channel with the lowest signal level.
4. Set the selected channel center frequency as the operating frequency of the wireless device.
   a. Establishing a link with the subscriber devices.
   b. Data transmission.
5. After 24 hours, rescan and reselect the frequency (steps 2-4). The re-scanning time can be manually set.

An example of the dynamic frequency selection algorithm is shown in the video 1.

The base station (BS) sector and the subscriber (CPE) are installed and configured to establish a wireless link between two buildings and the dynamic frequency selection feature is activated on the BS. After power-up, the BS begins a sequential available frequency channels scanning, adding the signal
levels in the DFS table. The table has the following form:

<table>
<thead>
<tr>
<th>Frequency channel</th>
<th>Signal level, dBm</th>
</tr>
</thead>
<tbody>
<tr>
<td>F1</td>
<td>-85</td>
</tr>
<tr>
<td>F2</td>
<td>-80</td>
</tr>
<tr>
<td>F3</td>
<td>-91</td>
</tr>
</tbody>
</table>

The BS device analyzes the table and selects the frequency channel with the minimum signal level value, i.e. channel F3. The selected channel center frequency is set as operational.

The center frequency changing causes an interruption in the wireless connection. The CPE device starts to look over the allowed frequency channels list, while searching for a BS device. After the BS is detected, the wireless devices perform the association, establish a link, and the data exchange resumes.

The radar detection principle

The radar detection algorithm operation can be described by the following steps:

1. Turning on the device.
2. Sequential frequency channel scanning. The device scans the air in accordance with the configured frequency grid.
   a. Signals over the air are checked whether they belong to the known radars.
   b. By default, the scan duration on each frequency channel is 3 seconds and this parameter is configurable.
   c. The total scan duration depends on the channels’ number in the frequency grid.
3. Frequency channels with radar detected are marked as inaccessible for use.
   a. The channel is excluded from the table for 30 minutes.
4. The next scan repeats the procedure for radar detection (steps 2-3).
   a. The radar detection procedure is performed simultaneously with the DFS mechanism operation.

An example of the radar detection algorithm is shown in the video 2.

The BS and the CPE are installed and configured to establish a wireless link between two buildings and the BS supports the dynamic frequency selection mechanism with radar detection. A meteorological radar is installed on the building next to the BS and using frequency channel F3. Same as in the previous example (see video 1), the BS starts a sequential available frequency channels scanning and fills in the table. During the F3 frequency channel scanning the BS detects the radar operation. Although the signal level in channel F3 is lower than in other channels, it is excluded from the decision-making process. Thus, the updated table looks as follows and the BS sets F1 as the operating frequency:

<table>
<thead>
<tr>
<th>Frequency channel</th>
<th>Signal level, dBm</th>
</tr>
</thead>
<tbody>
<tr>
<td>F1</td>
<td>-85</td>
</tr>
<tr>
<td>F2</td>
<td>-81</td>
</tr>
</tbody>
</table>

Instant DFS

The DFS mechanism disadvantage is the inability to quickly assess the radio parameters and timely change the operating frequency in accordance to the situation. A first solution is to perform the scan more frequently, however, it should be understood that the time spent on updating the information about the radio parameters is not used to transmit data, i.e. the communication system performance decreases.

InfiNet devices use a proprietary technology called Instant DFS, which allows to obtain current information about the radio state, without interrupting the connection.

Instant DFS operation principles

The Instant DFS operation principle is similar to the described DFS algorithm, but it has the following differences:

- Sequential frequency grid channels scanning is performed continuously, not at a selected time. This allows the device to operate with real time information about the radio parameters without stopping the data transfer process. For the devices of the InfiLINK 2x2 and InfiMAN 2x2 families this is implemented using an additional radio module, for the InfiLINK XG family devices - by scanning the air during the guard intervals.
In case of detecting a less interfered frequency channel, a switch with the operating frequency is performed, without interrupting the data transmission process. The InfiLINK 2x2 and InfiMAN 2x2 families devices, which have two radio modules, distribute among themselves a set of frequency channels that need to be scanned after they are powered-on, so the scan is performed two times faster.

An example of the proprietary Instant DFS mechanism is shown in the video 3:

- The BS and CPE devices are installed and configured to establish a wireless link between two buildings and the Instant DFS technology is activated on the BS. The initial operating frequency selection is similar to the DFS algorithm (see video 1), therefore, it is supposed that the devices have already established a connection and started data exchange.
- Initially, the BS performs data transmission and reception using frequency channel F3 and scans channel F1. After the scan is completed, the BS device updates the radio status table. Since the F3 channel, which is currently used is the most clear of interferences, the BS does not make any changes.
- In the second step, the BS transmits and receives data using frequency channel F3 and scans channel F2. The interference level on the F2 frequency channel has significantly improved: the signal level has decreased from -80 dBm to -90 dBm. Now channel F2 performs the best, so the BS begins the process of changing the operating frequency.
- In order to perform the frequency change without interrupting the connection, the BS generates a broadcast request with an overhead message, which indicates the new operating frequency F2. The frequency is changed on the BS after sending the broadcast message, and on the CPE after receiving this message.
- In the third step, the BS performs the transmission and reception of data using frequency channel F2 and scans channel F3. The obtained scan results do not lead to a change in the operating frequency; therefore, data continues to be transmitted through channel F2. Scanning is repeated cyclically in accordance with the set frequency grid.

Instant DFS application patterns

Devices with Instant DFS support can be used in point-to-point and point-to-multipoint topologies. Please note that the scan results are valid only for the received signal, therefore:

- In point-to-point topologies, it is recommended to use the Instant DFS technology on both devices. During operation, the devices will exchange the scan results and the decision about the frequency selection will be made taking into account the interference on both ends.
- If in the point-to-point topology it is not possible to use two devices with Instant DFS, then the device with Instant DFS needs to be installed on the site with the highest interference levels.
- In point-to-multipoint topologies, if it is not possible to have all the devices with Instant DFS support, the best option would be to install an Instant DFS device as a base station sector.

Instant DFS implementation in the InfiNet devices

Instant DFS proprietary technology support is implemented for the InfiLINK 2x2 and InfiMAN 2x2 families operating in the 5 GHz frequency band through the additional radio module installation. Lowercase letter “s” in the device part number indicates the presence of the second radio module, for example, R5000-Mmxbs/5.300.2x500.2x16.

All InfiLINK XG family devices operating in the 5 GHz frequency band support the Instant DFS technology.
